Enzymology

- Many biochemical reactions would, of their own accord, proceed at a rate that is far too slow to be of use.
- Enzymes are natural catalysts which greatly increase the rate of reaction.

Michaelis-Menten equation

For many enzymes the rate of reaction is determined by the *Michaelis-Menten* equation

$$v = \frac{V_{\max} s}{K_M + s}$$

Here V_{\max} is the maximum rate at which substrate is turned into product and K_M is the *Michaelis* parameter, the substrate concentration at which the rate of reaction is 50% of its maximum.

Enzymologists are interested in the values of these parameters, and also in derived quantities such as the specificity constant V_{\max}/K_M .

Parameter Estimation

- The enzymologist observes the values of v , v_i , at a series of substrate concentrations, s_i , $i=1,\dots,n$.
- Parameters are estimated by fitting the Michaelis-Menten equation to these data
- Will start with the model

$$v_i = \frac{V_{\max} s_i}{K_M + s_i} + \mathbf{e}_i$$

with \mathbf{e}_i a residual with zero mean and constant variance.

- Substantial history to fitting this model, and also some concerns over the use of this model (Ruppert, Cressie and Carroll, 1989; Nelder, 1991; also Cornish-Bowden 1995)

Design Problem

- How should the experimenter choose the substrate concentrations?
- Some work on this: Currie (1982) in *Biometrics*, also Duggleby (1979) and Endrenyi & Chan (1981) in enzymology literature
- Depends on the aims of the experiment
- Will be assumed that the aim is to estimate the parameter(s) and to do this with maximal precision.
- Will not consider studies where the aim is to differentiate between different types of reaction.

Expected Information matrix

For the above model the expected information matrix is proportional to

$$\mathbf{s}^{-2}NM = \mathbf{s}^{-2}N \left(\begin{array}{c} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^2} \\ -V_{\max} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^3} \quad V_{\max}^2 \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^4} \end{array} \right)$$

We assume that N observations are made at m distinct substrate concentrations. The number of observations at s_j is $N\mathbf{h}_j$, where $\mathbf{h}_j \geq 0$, $\sum \mathbf{h}_j = 1$.

Locally D-optimal design

The log of the determinant of the above can be written as the log of :

$$\Delta = \left(\prod_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^2} \right) \left(\prod_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^4} \right) - \left(\prod_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^3} \right)^2$$

where terms not involving the design points $\mathbf{x} = (s, \mathbf{h})$ have been omitted

Depends on K_M (though not on V_{max}).

For $m=2$ writing $y_j = s_j/(K_M + s_j)$ gives the above as

$$\mathbf{h}_1 \mathbf{h}_2 y_1^2 y_2^2 (y_1 - y_2)^2$$

The optimal design has $\mathbf{h}_1 = \mathbf{h}_2 = 1/2$ and $y_1 = 1/2$ and $y_2 = 1$, i.e. $s_1 = K_M, s_2 = \infty$.

(Currie, Duggleby, Endrenyi)

Bayesian D-Optimal design

Find design by maximising $E_{\text{prior}}(\log \det(\mathbf{s}^{-2}NM))$

Specify knowledge about K_M through a prior.

Objective factors into $f(N)+f(\sigma)+f(V_{\max})+f(K_M, \text{design})$

So no need to specify a prior for V_{\max} , only marginal for K_M

Convenient to assume prior has finite support on K_L, K_U . These to be specified by investigator.

Some parsimony achieved by scaling: write $s_j = K_U t_j$, $K_M = K_U \mathbf{k}$

(with $K_L/K_U = \mathbf{k}_L < \mathbf{k} < 1$).

Two priors: 1. \mathbf{k} uniform over its range 2. $\log \mathbf{k}$ uniform over its range.

Optimal Bayesian 2-point design

A bit of an indulgence, but analytical progress can be made here.

Designs all give equal weight to both points.

Larger concentration is at infinity

Smaller concentration t_1 is at the solution to
$$\mathbb{E}_{\mathbf{p}} \left(\frac{\mathbf{k} - t_1}{\mathbf{k} + t_1} \right) = 0$$

An approximate solution is therefore $t_1 = \mathbb{E}_{\mathbf{p}}(\mathbf{k})$, which fits with locally optimal solution. Also, Jensen's inequality shows that in fact $t_1 \leq \mathbb{E}_{\mathbf{p}}(\mathbf{k})$.

For prior 1, t_1 is 0.397 ($\mathbf{k}_L = 0$); for prior 2, $t_1 = \sqrt{\mathbf{k}_L}$.

Optimal Bayesian designs

- Search numerically for optimal design for $m = 3, 4, \dots$
- Use NAG software for quadrature and optimisation.
- Search for $0 \leq t_j \leq T$, and $\mathbf{h}_j \geq 0$, $\sum \mathbf{h}_j = 1$, where T is just some ‘large’ scaled concentration, arbitrarily set at 10 (sensitivity to choice can be explored)

Optimal designs

k_L	t							h				
Uniform on k												
0	0.02	0.39	10				0.02	0.49	0.49			
Uniform on $\log k$												
10^{-2}	0.04	0.33	10				0.26	0.30	0.44			
10^{-5}	4.4E-5	4.9E-4	3.8E-3	2.9E-2	2.9E-1	10	0.12	0.10	0.11	0.14	0.23	0.30

All of these can be confirmed to be optimal from the ‘derivative’ plots

$d(t) = E_p [trM(\mathbf{x}^*)^{-1} m(t, \mathbf{k})]$, is ≤ 2 if \mathbf{x}^* is optimal and $= 2$ only at points in \mathbf{x}^*

Alternative criteria

There may be interest in simply finding designs which are good for estimating K_M or alternatively V_{max}/K_M .

For former, criterion is to minimise

$$\log \left[\sum_{j=1}^m \mathbf{h}_j \frac{t_j^2}{(\mathbf{k} + t_j)^2} \right] - \log f(\mathbf{k}; \mathbf{x}, m)$$

where $f(.,.)$ denotes the determinant in the preceding criterion.

Locally optimum design ($\mathbf{k}=1$), gives $s_1 = K_M/\sqrt{2}$, $s_2 = \infty$; $\mathbf{h}_1 = 1/\sqrt{2}$.

For specificity ratio, V_{max}/K_M optimal designs are based on

$$\log \left[\sum_{j=1}^m \mathbf{h}_j \frac{t_j^4}{(\mathbf{k} + t_j)^4} \right]$$

$$- \log \left[\sum_{j=1}^m \mathbf{h}_j \frac{t_j^2}{(\mathbf{k} + t_j)^2} \sum_{j=1}^m \mathbf{h}_j \frac{t_j^4}{(\mathbf{k} + t_j)^4} - \left(\sum_{j=1}^m \mathbf{h}_j \frac{t_j^3}{(\mathbf{k} + t_j)^3} \right)^2 \right]$$

Locally optimum design has same design points as for K_M but different weights.

s_j	$K_M/\sqrt{2}$	∞
K_M	$1/\sqrt{2}$	$1-1/\sqrt{2}$
V_{max}/K_M	$\frac{1}{2} (1+1/\sqrt{2})$	$\frac{1}{2} (1-1/\sqrt{2})$

Optimal Designs

k_L		t					h					
Optimal designs for $\text{var}(\hat{K}_M)$												
10^{-2}		0.029	0.269	10.0		0.451	0.319	0.230				
10^{-5}	4.0E-5	4.5E-4	3.6E-3	2.7E-2	2.4E-1	10	0.22	0.17	0.16	0.16	0.18	0.12

- Designs need greater weight at lower concentrations than for D-optimal designs.
- Intuitively reasonable as the relative importance of information about V_{max} is less important.

Why the point at 10?

- In all designs found so far, some weight has been given to a point at the upper limit of the range for the (scaled) substrate concentrations.
- This gives information about V_{\max} : essential even when interest is focussed solely on K_M .
- Also, designs apply to all priors on (V_{\max}, K_M) , including those with very specific prior knowledge about V_{\max} .
- If there is good prior knowledge about V_{\max} , why the point at 10?

Answer is that criterion

$$E_p \left(\log \det \left[\mathbf{S}^{-2} N \left(\begin{array}{c} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^2} \\ -V_{\max} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^3} \end{array} \quad V_{\max}^2 \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^4} \right) \right] \right)$$

does not take prior information into account in the *analysis*. To do so requires criterion to be modified to:

$$E_p \left(\log \det \left[\mathbf{S}^{-2} N \left(\begin{array}{c} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^2} \\ -V_{\max} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^3} \end{array} \quad V_{\max}^2 \sum_{j=1}^m \mathbf{h}_j \frac{s_j^2}{(K_M + s_j)^4} \right) + R \right] \right)$$

R^{-1} being the dispersion matrix of the prior.

Prior Precision Matrix, R

Reasonable to take the priors for V_{\max} and K_M to be independent.

$$R = \begin{pmatrix} 1/\text{var}(V_{\max}) & \\ & 1/\text{var}(K_M) \end{pmatrix} = \begin{pmatrix} \mathbf{s}_V^{-2} & \\ 0 & K_U^{-2} \text{var}(\mathbf{k})^{-1} \end{pmatrix}$$

Optimal design now depends on \mathbf{s} and N . However, write R^* as:

$$R^* = \frac{\mathbf{s}^2}{N} R = \begin{pmatrix} 1/(N\mathbf{l}) & \\ 0 & \mathbf{s}^2/(N \text{var}(K_M)) \end{pmatrix} = \begin{pmatrix} 1/(N\mathbf{l}) & \\ 0 & \mathbf{s}^2 K_U^{-2} \text{var}(\mathbf{k})^{-1} / N \end{pmatrix}$$

where $\mathbf{l} = \mathbf{s}_V^2 / \mathbf{s}^2$ is the prior variance of V_{\max} in units of the RMS. New criterion is expectation over prior of log of

$$\Delta = \left(\sum_{j=1}^m \mathbf{h}_j \frac{t_j^2}{(\mathbf{k} + t_j)^2} + \frac{1}{N\mathbf{l}} \right) \left(\sum_{j=1}^m \mathbf{h}_j \frac{t_j^2}{(\mathbf{k} + t_j)^4} + \frac{1}{N\mathbf{l}\tilde{V}^2 \text{var}(\mathbf{k})} \right) - \left(\sum_{j=1}^m \mathbf{h}_j \frac{t_j^2}{(\mathbf{k} + t_j)^3} \right)^2$$

where \tilde{V} is V_{\max} scaled by its prior SD.

Prior specification

Prior for V_{\max} is $N(V_0 \mathbf{s}_V, \mathbf{s}_V^2)$, {so for \tilde{V} is $N(V_0, 1)$ }.

Prior for \mathbf{k} is either the prior of the associated uniform disn. or improper, $\text{var}(\mathbf{k})^{-1}=0$.

Note that if improper prior used for \mathbf{k} then objective function does not depend on V , except through $1/(NI)$, so expectation is a one-dimensional integral.

Designs obtained for Improper Prior

All have $N=5$

$\kappa = 0.01$		
t	h	l
0.036	0.27	10
0.33	0.31	
10	0.42	
0.036	0.33	1
0.34	0.37	
10	0.31	
0.037	0.48	0.1
5.0	0.52	

$\kappa = 0.001$		
t	h	l
0.004	0.20	10
0.04	0.16	
0.30	0.28	
10	0.37	
0.004	0.23	1
0.04	0.20	
0.32	0.33	
10	0.24	
0.006	0.46	0.1
0.18	0.54	

A Glimpse of other error models

Ruppert *et al.* (1989) discussed constant variance assumption and a weighting/transformation approach.

Nelder (1991) suggested application of extended quasi-likelihood to explore models with $Var(y) = \mathbf{S}^2 \mathbf{m}^V$ with a data-determined value for \mathbf{z} (in Nelder's example a value between 1 and 2 was obtained)

We explore the cases $\mathbf{z} = 1$ and 2

Information matrix is $\mathbf{S}^{-2} \frac{\partial \mathbf{m}^T}{\partial \mathbf{b}} \text{diag}(\mathbf{m}_i^V) \frac{\partial \mathbf{m}}{\partial \mathbf{b}}$

Information matrix

$$\begin{pmatrix} V_{\max}^{-V} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^{2-V}}{(K_M + s_j)^{2-V}} & \\ -V_{\max}^{1-V} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^{2-V}}{(K_M + s_j)^{3-V}} & V_{\max}^{2-V} \sum_{j=1}^m \mathbf{h}_j \frac{s_j^{2-V}}{(K_M + s_j)^{4-V}} \end{pmatrix}$$

D-Optimal designs for $\mathbf{z} = 1$ and searching using $T = 10$ gives

k_L	t				\mathbf{h}					
Uniform on \mathbf{k}										
0		0.16	10			0.5	0.5			
Uniform on $\log \mathbf{k}$										
10^{-2}	0.02	0.16	10		0.32	0.22	0.46			
10^{-5}	3.0E-5	5.7E-4	7.7E-3	1.1E-1	10	0.16	0.13	0.15	0.23	0.33

For $\mathbf{z} = 2$ determinant of information matrix becomes

$$\sum_{j=1}^m \mathbf{h}_j \sum_{j=1}^m \mathbf{h}_j \frac{1}{(\mathbf{k} + t_j)^2} - \left(\sum_{j=1}^m \mathbf{h}_j \frac{1}{(\mathbf{k} + t_j)} \right)^2 = \sum_{j=1}^m \mathbf{h}_j (z_j - \bar{z}_w)^2$$

$$z_j = (\mathbf{k} + t_j)^{-1}$$

This is maximised by a two-point design, with concentrations at 0 and T , equally weighted (for any prior)

Some Efficiencies

Duggleby suggested equal numbers of observations at each of

$$K_M/4, K_M/2, K_M, 2K_M, 4K_M.$$

What is efficiency of this design?

We have a prior for \mathbf{k} , and it seems reasonable to use the mean of the prior to compare Bayesian designs with Duggleby's design. Scaling this suggests comparing optimal designs with t_j 's equal to:

$$\bar{\mathbf{k}}/4, \bar{\mathbf{k}}/2, \bar{\mathbf{k}}, 2\bar{\mathbf{k}}, 4\bar{\mathbf{k}}$$

Criterion is $\exp(E/p)$ where p is no. parameters and

$$E = E_p \left[\log \det(M(\mathbf{x}^*)^{-1}) \right] - E_p \left[\log \det(M(\mathbf{x}_{Duggleby})^{-1}) \right]$$

k_L	D-optimal	K_M
Uniform		
0	0.51	0.4
Log-Uniform		
10^{-2}	0.52	0.38
10^{-5}	0.26	0.08

Amended designs

k_L	D-optimal	K_M
Uniform		
0	0.81	0.73
Log-Uniform		
10^{-2}	0.85	0.74
10^{-5}	0.39	0.14

General remarks

- Optimal designs can have few points
- Reliant on idea that there is a single purpose behind the study
- Using a prior distribution increases the number of points in the design, as a ‘hedge’ against the uncertainty around the values of the parameters
